Abstract

Objective: To assess the role of DWI and the ADC in differentiating between local tumor recurrence and benign breast changes after breast conservative surgery.

Patients and Methods: 26 patients with breast conservation surgery were included in our study. MRI study was done using fat-suppressed T2- weighted fast spin-echo, STIR, T1-weighted fast spin-echo. DWI series were acquired using echo planar imaging pulse sequences incorporating with diffusion gradients and finally dynamic contrast study.

Results: Among the twenty sex patients underwent MR imaging in our study, 7 patients were diagnosed at histopathology as local tumor recurrence, 11 patients had surgical scarring, 6 patients had seromas, one patient had hematoma and one patient had fat necrosis. Local tumor recurrence showed lower ADC values (mean ADC=0.95 ± 0.37x10⁻³ mm²/s) than that of benign lesions (mean ADC=1.69 ± 0.16x10⁻³ mm²/s). The sensitivity and specificity of DWI in the differentiating local tumor recurrence from benign breast lesions were 100% and 94.7%, respectively.

Conclusion: DWI is easy to obtain in short scan time, easy to evaluate and ADC values can differentiate between local tumor recurrence and benign breast changes after breast conservation surgery with high sensitivity & specificity.

Key Words: Diffusion-weighted imaging – Apparent diffusion coefficient – Breast lesions.

Introduction

WITH breast conservation therapy, the rate of recurrence is low but not zero. The statement that outcomes in women who undergo breast conservation are equivalent to the outcomes in women who undergo mastectomy is debatable. The trials that have been performed to date have shown that women who undergo breast conservation have a higher risk of local recurrence. Thus, disease free survival is not equivalent [1]. It was previously thought that local recurrence did not affect overall survival. However, it is now well accepted that local relapse does affect overall survival. Therefore, preventing local recurrence is considered as important as the early diagnosis of the primary breast cancer. The ability to prevent local recurrence requires more accurate staging and subsequent treatment; this is where MRI can play a critical role [2-4].

Architectural distortion and increased density at the lumpectomy site as well as post-treatment edema may impair accurate detection of recurrence at mammography and ultrasonography (US). Local-regional recurrences occur in approximately 5% of patients at 5 years with a local failure rate of approximately 1%-2.5% per year. In the immediate postoperative period, suspicious findings likely represent residual disease, whereas local recurrence typically occurs 3-7 years after breast conservation therapy. Early detection of local recurrence of breast cancer has been shown to significantly improve long-term survival [5].

Dynamic contrast material-enhanced magnetic resonance (MR) imaging has been shown to aid significantly in detection and characterization of primary and recurrent breast cancers [6,7]. The sensitivity of breast MR imaging for detection of residual and recurrent tumor in the post- breast conservation therapy is over 90% [8,9]. Breast
MR imaging has been shown to be useful in differentiating scar tissue from tumor recurrence; in particular, non-enhancing areas have a high negative predictive value for malignancy (88%-96%) [10,11].

Currently, there is much variability in use of breast MR imaging to follow-up women after BCT. The practice guidelines of the American College of Radiology state that breast MR imaging may be useful in women with a history of breast cancer and suspicion of recurrence when clinical, mammographic, or sonographic findings are inconclusive [12]. Although women with a previous diagnosis of breast cancer are at increased risk for a second diagnosis, an American Cancer Society panel concluded that the increased risk due to a personal history of breast cancer alone does not justify a recommendation for overall screening with MR imaging in women who have undergone breast conservation therapy [13].

Currently one of the most important indications for MRI is the differential diagnosis between cancer recurrence and surgical scar. In fact, breast MRI has become a common practice in the evaluation for recurrence of breast cancer. Both surgery and radiation can cause scarring with architectural distortion of the breast, which makes assessment of local recurrence difficult by means of clinical examination, mammography, and ultrasound. Post-treatment changes can mimic malignancy or obscure locally recurrent breast cancer. For these reasons, breast MRI is a useful tool in the evaluation of such patients [14-16].

Diffusion-weighted imaging (DWI) is an unenhanced MRI sequence that measures the mobility of water molecules in vivo and provides different and potentially complementary information to (Dynamic Contrast Enhancement) DCE-MRI. DWI is sensitive to biophysical characteristics of tissues, such as cell density, membrane integrity, and microstructure. Promising findings from preliminary DWI studies of the breast have shown significantly lower apparent diffusion coefficient (ADC) measures for breast carcinomas than for benign breast lesions or normal tissue [17-23]. The lower ADC in malignancies is primarily attributed to higher cell density causing increased restriction of the extracellular matrix and increased fraction of signal coming from intracellular water [17,18,24]. A recent study reported high accuracy for characterizing enhancing breast masses through a multivariate combination of DWI and DCE-MRI features [25].

Aim of the study:
The aim of our study was to assess the role of DWI and the ADC in differentiating between loco-regional tumor recurrence and benign breast changes after breast conservative surgery.

Patients and Methods

Between June 2009 and February 2013, 26 patients (age range, 25-68 years; mean age, 49 years) with breast conservation surgery (lumpectomy & partial mastectomy) were included in our study. Patients were imaged using conventional MRI, DWI and DCE-MRI before biopsy of their breast lesion. Approval for the study was obtained from the local ethical committee in the Alnoor specialist hospital, in Holey Makkah. Written informed consent was obtained from all patients before MRI. In all patients, MRI was performed bilaterally. Examinations were excluded if no diffusion weighted imaging had been performed, no measurable mass on DWI or less than one year of follow-up is not available.

MRI technique:

MRI examinations were performed using a 1.5-T MRI scanner (Magnetom Espree, Siemens Healthcare). Patients were examined in the prone position using a dedicated 4-channel phased array bilateral breast coil. Before administration of contrast media, axial bilateral fat-suppressed T2-weighted fast spin-echo, axial STIR, axial T1-weighted fast spin-echo and DWI series were acquired.

DW image was performed in axial slice orientation using echo planar imaging pulse sequences incorporating with diffusion gradients. DW EPI with fat suppression was applied using TR/TE of about 8400/98 ms, FOV of 340x170mm, matrix: 192x96 and a slice thickness of 4mm. Spectral pre-saturation with inversion recovery (SPAIR) was used for fat suppression. An acceleration factor of two was applied using the generalized auto-calibrating partially parallel acquisition (GRAPPA) of parallel imaging technique. Motion-probing gradients in three orthogonal orientations were applied with b values of 50, 400 and 800 using 3-scan trace calculation. Isotropic diffusion-weighted (trace) images were reconstructed for each b value. For quantitative analysis of the data acquired from DWI, ADC maps were automatically created using software provided by the MRI system manufacturer (Syngo, Siemens Healthcare) using three b values (50, 400, and 800s/mm²). We apply the DW sequences prior to the dynamic scan as the T1 relaxation due to the contrast agent
will cause changes to the inversion of the tissue and thus can have a strong impact.

Finally, dynamic axial bilateral breast images of fat-suppressed high-resolution T1-weighted 3D fast gradient-echo images were sequentially acquired. Five measurements were acquired one before and four after the administration of contrast media. For the dynamic study, gadopentetate dimeglumine (Magnevist) was administered IV using a power injection at a dose of 0.1 mmol/kg of body weight at a flow rate of 2mL/s, followed by flushing with 25mL of saline. The parameters were as follows: TR/TE 4.2/1.6; flip angle 15º; FOV 340x340mm; matrix 512x410; thickness 0.9mm; acquisitions 1; and acquisition time 110 seconds. SPAIR for fat suppression and a GRAPPA acceleration factor of two for parallel imaging technique were also applied. DCE was done in 25 cases and contraindicated in one patient with renal failure on hemodialysis with GFR less than 30mL/min.

Results

Among the twenty sex patients undergoing MR imaging in our study, diagnosis of loco-regional tumor recurrence of breast carcinoma at the surgical site was pathologically proved in seven cases. Eleven patients had surgical scarring, six patients had seromas, one patient had hematoma and one patient had fat necrosis.

According to the ADC values (Table 1) seven lesions were local regional tumor recurrence (Fig. 1 and Fig. 2), and showed mean ADC values of $0.95 \pm 0.37 \times 10^{-3}$ mm$^2$/s and ADC range of (0.76-1.33 $\times 10^{-3}$ mm$^2$/s).

---

Fig. (1): Neoplastic recurrence. 48 year-old female submitted to right quadrantectomy 2.5 years ago for invasive ductal carcinoma. (A) Axial T1 WI & (B) Axial SITR demonstrate a right breast ill defined mass at the surgical scar. (C) DWI with b=800 shows a hyperintense mass (arrow). (D) ADC map shows hypointense lesion (arrow) with ADC value of about $1.09 \times 10^{-3}$ mm$^2$/s. (E) Post-contrast study displays marked enhancing mass. (F) Dynamic curve shows washout curve with peak enhancement at 1.5 minute.
In our study nineteen lesions were benign; 11 lesions were post-operative scarring (Fig. 3) and showed mean ADC values of $1.66 \pm 0.28 \times 10^{-3}$ mm$^2$/s and ADC range of $(1.35-1.86 \times 10^{-3}$ mm$^2$/s), 6 lesions were seromas (Fig. 4) and showed mean ADC values of $2.21 \pm 0.15 \times 10^{-3}$ mm$^2$/s and ADC range of $(2.13-2.73 \times 10^{-3}$ mm$^2$/s), one lesion were hematoma (Fig. 5) and showed mean ADC values of $0.39 \pm 0.16 \times 10^{-3}$ mm$^2$/s and ADC range of $(0.34-0.56 \times 10^{-3}$ mm$^2$/s) and one lesion was fat necrosis (Fig. 6) and showed mean ADC values of $0.141 \pm 0.26 \times 10^{-3}$ mm$^2$/s and ADC range of $(1.22-0.161 \times 10^{-3}$ mm$^2$/s).

All cases of local regional tumor recurrence in our study showed lower ADC values than benign lesions with ADC range of $0.76-1.33 \times 10^{-3}$ mm$^2$/s (mean ADC=$0.95 \pm 0.37 \times 10^{-3}$ mm$^2$/s) and were diagnosed pathologically as malignant breast lesions. All benign lesions showed higher ADC values with a range from $1.22-2.73 \times 10^{-3}$ (mean ADC=$1.69 \pm 0.16 \times 10^{-3}$ mm$^2$/s) except one case of hematoma showed lower ADC value ($0.34-0.56 \times 10^{-3}$ mm$^2$/s) and was diagnosed by conventional MRI. Figure seven shows box plots graphs of range and mean apparent diffusion coefficient (ADC) values for local regional neoplastic tumor recurrence and benign breast changes after breast conservation therapy in our study.

In our study, using a cutoff point $1.35 \times 10^{-3}$ mm$^2$/s, the sensitivity, and specificity for DWI in the differentiating local regional recurrence from benign breast lesions were 100% and 94.7%, respectively and total accuracy of about 96.2%.
Fig. (3): Scar tissue. 61 year-old female submitted to left quadrantectomy 1.5 years ago for ductal carcinoma. (A) Axial T1 GRE (VIBE) & (B) Axial SITR demonstrate a left breast ill defined lesion at the surgical site. (C) DWI with b=800 shows a hypointense ill defined lesion (arrow). (D) The ADC map shows hyperintense lesion (arrow) with ADC value of about 1.68 x 10^{-3} mm²/s. E- Post-contrast study shows minimally enhancing lesion (arrow). (F) Dynamic curve shows monophasic curve.

Fig. (4): Post-operative seroma. 36 year-old female submitted to left quadrantectomy 10 months ago for ductal carcinoma. (A) Axial T2 FS & (B) Post-contrast GRE (VIBE) demonstrate left breast fluid collection with surrounding granulation tissue and marked skin edema. (C) DWI with b=800 shows slightly hyperintense lesion (due to T2 shine through effect). (D) The ADC map shows hyperintense lesion with ADC value of about 2.46 x 10^{-3} mm²/s.
Fig. (5): Hematoma. 29 year-old female submitted to left lumpectomy 6 months ago for ductal carcinoma. (A) Axial T1WI displays left breast mass of central low signal intensity and peripheral hyperintensity. (B) T2 FS demonstrates left breast hyperintense mass. (C) DWI with \( b=800 \) shows hyperintense lesion. (D) The ADC map shows hypointense lesion with ADC value of about \( 0.39 \times 10^{-3} \) mm\(^2\)/s. (E) Post-contrast GRE (VIBE) shows marginal enhancement.

Fig. (6): Fat necrosis. 37 year-old female submitted to left lumpectomy 11 months ago for ductal carcinoma. (A) Axial T1WI and (B) T2 FS demonstrate left breast lesion of mixed signal intensities with fat areas (arrow). (C) DWI with \( b=800 \) shows mixed signal lesion (arrow). (D) The ADC map shows a lesion with ADC value of about \( 1.41 \times 10^{-3} \) mm\(^2\)/s (arrow). (E) Post-contrast GRE (VIBE) shows heterogeneous enhancement (arrow).
Discussion

Breast MRI is the widely accepted diagnostic approach for evaluating the breast. To improve the sensitivity of detecting breast cancer, several diverse techniques are used for breast MRI [21]. In particular, dynamic-enhanced MRI provides for evaluating multiple foci of carcinoma in the breast and it displays extremely high sensitivity for identifying breast cancer. However, dynamic-enhanced breast MRI has some disadvantages such as being time-consuming and costly, the possible side effects of the contrast media and the relative low specificity compared to mammography and ultrasonography [26-28].

Generally in biologic tissues, microscopic motion includes both the molecular diffusion of water and the blood microcirculation in the capillary network, and both diffusion and perfusion affect the ADC values. Because of the extent of micro-vessels in malignant breast tumor, the ADC value can be strongly affected by perfusion when the b value is small. A previous report insisted that b-values less than 750s/mm² are most effective for detecting breast tumors [29]. However, we used EPI with a b-value up to (800s/mm²) so we could obtain diffusion effects without significant image distortion.

In addition to conventional MRI, DWI has been reported as a useful technique for the discrimination between benign and malignant breast lesions [17, 21,22]. We believe that DWI has a potential role in improving the diagnostic performance of breast MRI. Our findings show that a quantitative analysis of ADC values can be used to distinguish loco-regional tumor recurrence from benign breast changes after conservative surgery. In our study, all cases of loco-regional tumor recurrence show high signal intensity on DWI and low ADC value on ADC map (Figs. 1,2) with high ADC values of 0.95±0.37 x 10⁻²mm²/s and ADC range of (0.76-1.33 x 10⁻³mm²/s) which is in accordance with recent study [30].

All cases of post-operative scarring in our study show low signal intensity on DWI and high SI on ADC map (Fig. 3) with high ADC values than loco-regional tumor recurrence. The mean ADC values of scars in our study measures 1.66 ± 0.28 x 10⁻³mm²/s with ADC range of about 1.35-1.86 x 10⁻³mm²/s. Multiple studies [31,32] stated that postoperative granulation tissue had a high ADC value (2.66 x 10⁻³mm²/s) which in agreement with our study. Recent meta-analysis has determined that an ADC value >1.2 x 10⁻³mm²/sec speaks for benignancy [33] and other recent study [34] stated that The average ADC for scar tissue was 1.89 x 10⁻³mm²/s and ADC range of about 1.43-2.20 x 10⁻³ which are in accordance with our results.

All cases of seromas in our study are hypointense on T1 W imaging, hyperintense on T2W imaging, and displays smooth peripheral enhancement (<4mm thickness) with contrast and show free diffusion with mean ADC values of 2.21 ± 0.15 x 10⁻³mm²/s and ADC range of (2.13-2.73 x 10⁻³mm²/s) which in agreement of previous studies [31,33,35].

In our study there is one case of hematoma with false positive result on DWI with loco-regional tumor recurrence with mean ADC values of 0.39 ± 0.16 x 10⁻³mm²/s and ADC range of 0.34-0.56 x 10⁻³mm²/s. However the lesion was diagnosed as hematoma from conventional MRI as the lesion displayed hyperintense on T1 W imaging, hypointense on T2W imaging, and shows minimal smooth marginal contrast enhancement which in accordance with previous studies [30,35].
Role of Diffusion-Weighted Imaging & Apparent Diffusion

In Conclusion:

Breast conservation surgery with high sensitivity and specificity for DWI in differentiating loco-regional tumor recurrence from benign breast lesions were 100% and 94.7%, respectively. The sensitivity & specificity of diffusion MRI in differentiating loco-regional tumor recurrence from benign breast lesions in our study is in agreement with previous studies [19,25,30,32,37] which showed the sensitivity & specificity of DWI in the differentiation between benign and malignant breast lesions were ranging from 81% to 97%, and from 80% to 100% respectively.

In Conclusion:

DWI MR imaging without contrast medium may provide diagnostic ability equivalent to that of contrast-enhanced MR imaging in detection of loco-regional tumor recurrence after breast conservation surgery. The advantage of DW imaging to help visualize loco-regional tumor recurrence after breast conservation surgery without the need for contrast medium could be advantageous in women with impaired renal function. DWI is easy to obtain in short scan time and easy to evaluate, and ADC values can differentiate between loco-regional tumor recurrence and benign breast changes after breast conservation surgery with high sensitivity & specificity.
